The Making of Dominant Vehicle Currencies

Evidence from DeFi
Jiahua Xu

How we reconstruct a route from one transaction

Direct swap

one transaction

Sequential vehicle route

one transaction

Parallel split

one transaction

Round trip

one transaction

Swap events in one transaction reveal sequential routes, parallel splits, and round trips.

Vehicle dominance is the share of indirect trade carried by an asset

MEASUREMENT

- Dominance is the share of indirect trade intermediated by asset k .
- Count share treats each route equally; value share weights routes by dollar value.
- Network measures capture how broadly k connects endpoint pairs.

Count-weighted dominance

Share of indirect routes that pass through k

Value-weighted dominance

Share of comparable routed value that passes through k

This transaction routes USDC into USDe through USDT

OBSERVED ROUTE

The trace shows that USDT was used. It cannot tell us whether a direct USDC–USDe route was available or cheaper at that moment.

Architecture changes routing opportunities

V1 mandatory hub

Only ETH-token pools: token-to-token execution must pass through ETH.

Hub use is imposed

V2 pair choice

Arbitrary pairs add a direct route; vehicle routes remain feasible.

Hub use becomes a choice

V3 range choice

LPs choose ranges and fees; active depth can favor direct pairs or vehicle spokes.

Opportunity shifts by pair

V4 net settlement

Two pools still execute; intermediate token movement may be netted.

Settlement and vehicle use can diverge

Architecture feasible rules

Exposure realised pool and route use

Calendar date timing only

The sample spans Uniswap V1 through V4

DATA

Routes are reconstructed transaction by transaction across the routed venue perimeter. Daily and weekly panels are derived from the same route units.

Vehicle dominance aggregates realised intermediary choices

Separate characteristics of the asset and route set

Network position

position of k in the feasible graph

Execution cost

which route returns more at the same state

Endpoint demand supplies the benchmark; network position and same-state route costs remain separate characteristics.

Why might one asset become the dominant vehicle?

Architecture opens routes; realised trades reveal which vehicle is used

Stablecoins regain the lead in routed value

Annual shares of observed vehicle routes; the figure does not attribute the changes to protocol design.

USDT drives the post-2024 rise in stablecoin intermediation

The value panel retains routes whose source, intermediary, and destination dollar values agree within 20%. Parity means that intermediary and endpoint shares are equal. USDT crosses parity by routed value; USDC remains above it in both years.

Pair activity and vehicle use: 94.9% of the gain

Supported value tells the same broad story. Stable share rises +42.8 pp, with +26.2 pp from activity weights among continuing pairs and only 0.0 pp from stable-for-native substitution within them.

Route-count accounting for ordered endpoint pairs, pooling single- and cross-venue routes on month-days observed in both endpoint years through 30 June. Matched markets also hold the calendar position and broad realised route scope alike. Neither comparison holds venue sequence, feasible alternatives, notional, liquidity, cost, or router state fixed.

Stablecoin use rises within each venue scope

The increase appears within both realised route scopes, so a change in the single- versus cross-venue mix cannot account for the aggregate rotation. Cross-venue status remains selected; the comparison does not identify an effect of integration, routing software, or protocol architecture.

Liquidity and vehicle use are linked; V4 often nets transfers

Liquidity allocation and route use

Each predicts the other at 1, 7, 14, and 30 days

Vehicle use also predicts more total LP capital after 14 and 30 days, but not at the shorter horizons.

Liquidity regressions include asset and date effects and the lagged outcome. The receipt comparison matches 500 V3 routes and 500 V4 routes by week, ordered endpoint pair, and intermediary; V4 routes are smaller on average, so the 18.6-point difference is descriptive and does not estimate a causal V4 effect.

Economic routing and physical settlement

k is transferred in 100% of receipts

the economic route remains; k is transferred in 81.4% of receipts

Cheaper challengers gain share as incumbents lose it

30-day outcome	$\hat{\beta}$	SE	t
Challenger vehicle-share response	4.825	0.366	13.17
Incumbent vehicle-share response	-3.872	0.420	-9.22
Challenger overtakes incumbent	9.947	0.486	20.48

$N = 57,989$ pair-candidate observations; 2,213 date clusters. Exact alternating-projection absorption and CR1 rank correction.

The estimates are large in the small set of pair-candidate observations we can follow. They remain descriptive because the panel does not compare each pair against a fixed set of feasible routes.

Current architecture changes do not provide a clean before–after comparison

	5%	10%	25%
Sustained entries	162 (0)	139 (0)	78 (0)
Substitution exits	79 (0)	69 (0)	54 (0)
Role disappearances	7 (3)	7 (3)	7 (3)
Immediate entry contrast	–	–	–
Immediate exit contrast	–	–	–

At every threshold, entries and exits coincide with changes in the comparison set or with the appearance and disappearance of vehicle roles. These windows therefore cannot separate an architecture effect from changes in which pairs and vehicles remain active.

A before–after estimate requires the same feasible alternatives before and after the architecture change.

Stablecoins regain the value lead as route counts approach parity

- Stablecoins lead routed value in 2022 and again in 2025–2026, but fall behind native assets in 2023–2024.
- USDT drives the post-2024 rise in excess stablecoin intermediation; USDC changes little.
- Pair activity and vehicle use account for almost all of the aggregate stablecoin gain. Their economic cause remains open.

Appendix map

Definitions and data

- A1 Route units and vehicle status
- A2 Asset types and backing regimes
- A3 Sample construction and exclusions

Reconstruction and validation

- A4 Exact transaction state
- A5 Protocol-specific state
- A6 Forced routes in V1

Robustness

- A7 Daily and weekly frequencies
- A8 Count and value weighting
- A9 Endpoint demand

Mechanisms

- A10 Capital, inventory, and depth
- A11 Coordination and integration
- A12–A13 References

A1. One reconstructed route is one unit

one route unit
two swap legs

- Each linked $i \rightarrow k \rightarrow o$ route is counted once.
- Asset k is classified as the intermediary on that route.
- Dominance is the share of route units or supported value carried by k .

A2. Stablecoin backing cannot be treated as fixed

Bars begin at public launch or the sample start for older tokens. DAI cells mark admissible backing; the dashed FRAX arrow is a governance target, not an observed collateral share.

A3. One route universe supports two measurements

Topology-valid routes remain in count evidence when dollar support is unavailable.
Box widths do not represent attrition.

Missing dollar support narrows value-weighted evidence; it does not erase a topology-valid route from the count evidence.

A4. State is reconstructed immediately before execution

- Pool events are applied in blockchain order from a verified starting state.
- Each route is quoted using the pool state immediately before the transaction.
- Missing state intervals are excluded, and their share of trading volume is reported.

A5. Each AMM family has a different state vector

	reserves or active liquidity	ticks	amplification	weights or scaling	rates or oracles	fees	hooks
Constant product	■	—	—	—	—	■	—
Concentrated liquidity	■	■	—	—	—	■	—
StableSwap families	■	—	■	—	■	■	—
Weighted pools	■	—	—	■	■	■	—
V4 singleton	■	■	—	—	—	■	□

The common object is the state immediately before execution.
The fields required to recover that state vary with the pricing rule.

■ required state

□ hooks outside comparison

A6. V1 forced routes have an on-chain signature

- Token-to-token execution emits two linked swaps through ETH.
- Matching ETH quantities distinguish protocol-imposed intermediation from unrelated bundled swaps.

same transaction, matching ETH flow

A7. Daily and weekly frequencies answer different questions

Missing target dates remain missing: row shifts and calendar months do not substitute for exact calendar links.

A8. Count and value define separate dominance margins

Both panels contain the same routes. Line widths are illustrative, and value weighting applies only on the stated valuation-support band.

A9. Endpoint demand and intermediary use are separate margins

Intermediary share

$$S_{k,t}^I = \frac{N_{k,t}^I}{\sum_j N_{j,t}^I}$$

How often asset k sits inside a route.

Endpoint share

$$S_{k,t}^E = \frac{N_{k,t}^{\text{in}} + N_{k,t}^{\text{out}}}{\sum_j N_{j,t}^{\text{in}} + N_{j,t}^{\text{out}}}$$

How often asset k is what traders buy or sell.

Excess use compares intermediation with endpoint demand on the same support.

A10. Capital, inventory, and depth are different objects

Capital is a stock. Depth and quotes depend on trade size and current pool state.

A11. Integration changes the routes that can be chosen

Feasible venue layers

realised
execution

Realised route topology

The analysis therefore separates opportunity-set reach from the composition of realised routes.

A11b. Venue scope and vehicle type differ in 2026

Integration and vehicle composition are separate margins in 2026

Ribbon width is the share of 2026 intermediation jointly classified by venue scope and intermediary type.

The ribbons classify realised intermediation jointly by venue scope and intermediary type. They describe selected routes; they do not identify an effect of integration or the unchosen opportunity set.
